

Roseburn Air Pollution Modelling

An assessment of the Council Air Study published 14th Oct 2019 by John Lamb, retired SEPA expert with twenty years' experience in air pollution.

Background

“Since December 1997 each local authority in the UK has been carrying out a review and assessment of air quality in their area. This involves measuring air pollution and trying to predict how it will change in the next few years. The aim of the review is to make sure that the national air quality objectives will be achieved throughout the UK by the relevant deadlines. These objectives have been put in place to protect people's health and the environment. If a local authority finds any places where the objectives are not likely to be achieved, it must declare an Air Quality Management Area.” Defra ¹

Roseburn Terrace is part of a City Centre Air Quality Management Area (AQMA) that was designated by City of Edinburgh Council (CEC) in 2001, because the concentrations of nitrogen dioxide (NO₂) were exceeding the annual mean and 1-hourly air quality objectives.

Measuring nitrogen dioxide in Roseburn Terrace

CEC has used passive diffusion tubes (PDT) to measure NO₂ inside Roseburn Terrace since 2005. The measurements are published in a series of annual reports ², and they show that the annual mean objective was exceeded every year from 2005 to 2009. These measurements have also shown that the concentrations on the south side of the Terrace are consistently higher than the north. This is expected, because Roseburn Terrace is a text book Street Canyon (see appendix 1).

The concentrations of NO₂ on the north side of the terrace dropped below 40 µg.m⁻³ in 2009, and are still below the annual mean threshold value.

Unfortunately, CEC stopped measuring NO₂ on the south side of the street in 2009 (even though these measurements were consistently higher than the north side) therefore there are no data for the period 2010-2016. A mean leeward/windward ratio was calculated using data for 2005-2009 and this was used to calculate indicative figures for the missing years (see Table 1). These calculated figures (in red) suggest that the annual mean objective was likely to have been exceeded on the south side of the street, throughout this period. A PDT was returned to the south side of Roseburn Terrace in 2017 and the leeward/windward ratio was found to be 1.3 - confirming that the use of the 1.34 ratio was reasonable.

It was found that CEC had not followed the official guidance when it corrected PDT data ³ and published measurements for Roseburn Terrace are lower than they would have been if the guidance had been followed correctly. For example, in the case of 2017, the Council published

*This figure is wrong and it should be 40.3

It is important to note that the parking bays provide a space in which NO_2 can dilute before it arrives at the PDT, but the concentrations of NO_2 still exceed the annual mean objective on the south side of Roseburn Terrace. If the parking bays did not exist, the NO_2 could not dilute, therefore the figures in Table 1 would be higher.

The parking bays help to protect residents from the effects of pollution

Studies have shown that the concentrations of NO_2 fall rapidly as the distance from the traffic increases. This “Fall-off in NO_2 concentrations with distance from the road” is well documented and is described in paragraphs 7.77 to 7.79 of the UK and Scottish Government’s Technical Guidance document, LAQM TG.16.

This was put to good use when Dundee City Council (DCC) measured high concentrations of NO_2 outside a residential property in the centre of the city. The Council officers understood that the concentrations of NO_2 reduce with distance, so DCC moved traffic one lane away from the residential building and it has reported a 19% reduction in the concentrations of NO_2 .⁴

A similar situation exists in Roseburn Terrace. The parking bays push traffic one lane away from the residential buildings, creating a gap in which exhaust gases can dilute before they arrive at the façade of the buildings. The parking bays are therefore helping to protect residents and local retailers from the effects of traffic pollution. If these bays were to be removed, traffic would move one lane closer to the buildings. The exhaust gases will no longer have room to dilute, so the concentrations of NO_2 on the leeward side of a street canyon will be higher - adding to the already high levels of pollution at this side of Roseburn Terrace. The reverse of what was achieved in Dundee.

⁴ Dundee City Council’s Updating and Screening Assessment Report, 2015

The cycling lobby has pointed out that bicycles do not emit gases, so how can the pollution get worse. It is nothing to do with the cyclists, it is about the design and layout of the street and the way traffic passes through it. Street design is as important as the number and type of vehicles that pass through it - a reduced number of vehicles can still cause an air quality problem in a poorly designed street.

Figure 1: View of Roseburn Terrace (looking east) is showing how parked vehicles push traffic into the outer lane, increasing the distance between the traffic and the passive diffusion tube (on the grey post) and the shops/residential properties. Through traffic defaults to the outer lane even when there are no parked vehicles.

Roseburn Terrace Modelling Study

CEC commissioned a computer dispersion model that has considered 1-hourly concentrations of NO₂ in Roseburn Terrace during the busy morning and evening periods (5 hours per day, Monday to Friday).

There are no reported exceedances of the 1-hourly objective for NO₂ in Scotland, so there was no requirement to model this standard. Modelling the 1-hourly concentrations will show that there is not a problem. It would have been preferable to model the annual mean concentrations of NO₂, because compliance with this standard has proved to be problematical at many locations across the whole of the United Kingdom - including Roseburn Terrace.

There is no clear relationship between the 1-hourly concentrations and the annual mean concentrations, so modelling the 1-hourly will not show how changes to the road layout will affect the annual mean concentrations. For example, the monitoring device on St. John's Road recorded exceedances of the 1-hourly and annual mean air quality objectives. As the engine technologies improved over the years, the emissions of NO₂ slowly reduced and the 1-hourly mean exceedances stopped in 2012 – but the annual mean objective continued to be exceeded for another 6 years. See Appendix 3 for details.

Reasons for not accepting the findings of the Roseburn Terrace modelling study

1. **The model has only considered 1-hourly concentrations.** This is of little relevance in the case of Roseburn Terrace, because long-term monitoring has shown that it is the annual mean concentration of NO₂ that is at risk of being exceeded on the south side of the street, not the 1-hourly mean.
2. **The study has not assessed the implications for the health of the people who live and work in Roseburn Terrace.**
3. **The model has only considered 5 hours of traffic per day, Monday to Friday.** This is a busy arterial route and traffic passes through Roseburn Terrace 24 hours a day, seven days a week. This study should have considered all traffic over a period of one year.
4. **This is very important - model has not been validated.** *“Model validation refers to the general comparison of modelled results against monitoring data carried out by model developers. The model used should have some form of published validation assessment available and/or should be recognised as being fit for purpose by the regulatory authorities.”*⁵ The Roseburn Terrace model has not (and cannot) be validated, because there are no 1-hourly monitoring data for this location. CEC is unable to prove that this model is representative of the conditions that currently exist, or may exist within Roseburn Terrace.
5. **The modelling study has generated data that appears to contradict the monitoring data.** The model suggests that the concentrations of NO₂ on the north side of the Terrace are higher than those on the south. This contradicts 13 years of monitoring data that have consistently shown that the highest concentrations exist on the south side of Roseburn Terrace. If the model had focused on the annual mean concentrations (as stated above), it could have used local monitoring data to test the model, to see if it was performing correctly. This would have provided greater confidence in the results (see Appendix 4).
6. **This is not an independent assessment:** this model was set up and run by the same company that has worked with City of Edinburgh Council to design the CCWEL, therefore the model is likely to generate modelling results that will support claims that air quality will improve.

⁵ Local Air Quality Management Technical Guidance TG.16, Para 7.509

Appendix 1: Street Canyon

Roseburn Terrace is a text book example of a street canyon "... where, the highest levels of air pollution often occur and the larger targets of impact are concentrated. The natural ventilation of urban streets is reduced mainly due to the presence of buildings. Within the urban canopy, wind vortices, low-pressure areas and channelling effects may be created under certain meteorological conditions, giving rise in some cases to air pollution hotspots. For example, high concentration levels have been often observed on the leeward side of regular canyons under perpendicular wind conditions."⁶ The orientation of the street - in relation to the prevailing wind - is an important consideration, because when a canyon is perpendicular to the prevailing wind direction, the dispersion of atmospheric pollution is extremely poor. The prevailing wind direction in Edinburgh is from the south west and almost perpendicular to the orientation of Roseburn Terrace.

Slow moving, congested traffic and vehicles accelerating from a standing start will emit more pollution. Additional traffic lights will add to the problem. The exhaust emissions become trapped between the buildings where they get recirculated, resulting in higher concentrations of pollutants on the leeward (south) side of the street, as shown below. Council monitoring on both sides of the street has confirmed that the concentrations of NO₂ are approximately 30% higher on the leeward side of Roseburn Terrace.

Figure 1: Schematic drawing showing environmental conditions that would exist in Roseburn Terrace (looking east to west)

Source: <http://www.intechopen.com/books/air-quality-models-and-applications/urban-air-pollution-modeling>

The proposed changes to the road layout will move traffic from the less polluted windward side of the street, to the more polluted leeward side. Traffic will also be moved one lane closer to the façade of the building, resulting in higher concentrations of NO₂ in an area where the levels are already sitting on the annual mean threshold.

Appendix 2: Passive Diffusion Tube Measurements in Roseburn Terrace

LAQM TG16 (Paragraph 7.79 states) clearly states “When using the NO₂ fall-off with distance calculator, it is important to justify the distances used in the calculation tool, as there may be circumstances when it is appropriate to treat the edge of the road (described within the tool as being the ‘kerb’) as being the edge of the carriageway with flowing traffic rather than the physical kerb, e.g. on some urban roads where the first lane is used for parking and therefore the flowing traffic is away from the physical kerb.”

City of Edinburgh Council has ignored the parked vehicles and used the edge of the kerb to correct measurement data. This has produced a figure that is below the statutory 40 µg.m⁻³ standard. If it had followed the guidance as described, the corrected figure is higher and slightly above the annual mean standard.

	CEC correction	LAQM TG16 correction
Distance of PDT from kerb	0.5m	3.0m
Distance Kerb to receptor	2.7m	4.5m
Background Concentration	17 µg.m ⁻³	17 µg.m ⁻³
Roadside (diluted) measurement*	43 µg.m ⁻³	43 µg.m ⁻³
Corrected measurement at facade	35 µg.m ⁻³	40.3 µg.m ⁻³

Passive diffusion tube measurement (south side of Terrace)

Annual Hourly Mean	43	µg/m ³	Ratified	99% DC
Max Daily Mean	96	µg/m ³	Ratified	99% DC
Max Hourly Mean	298	µg/m ³	Ratified	99% DC

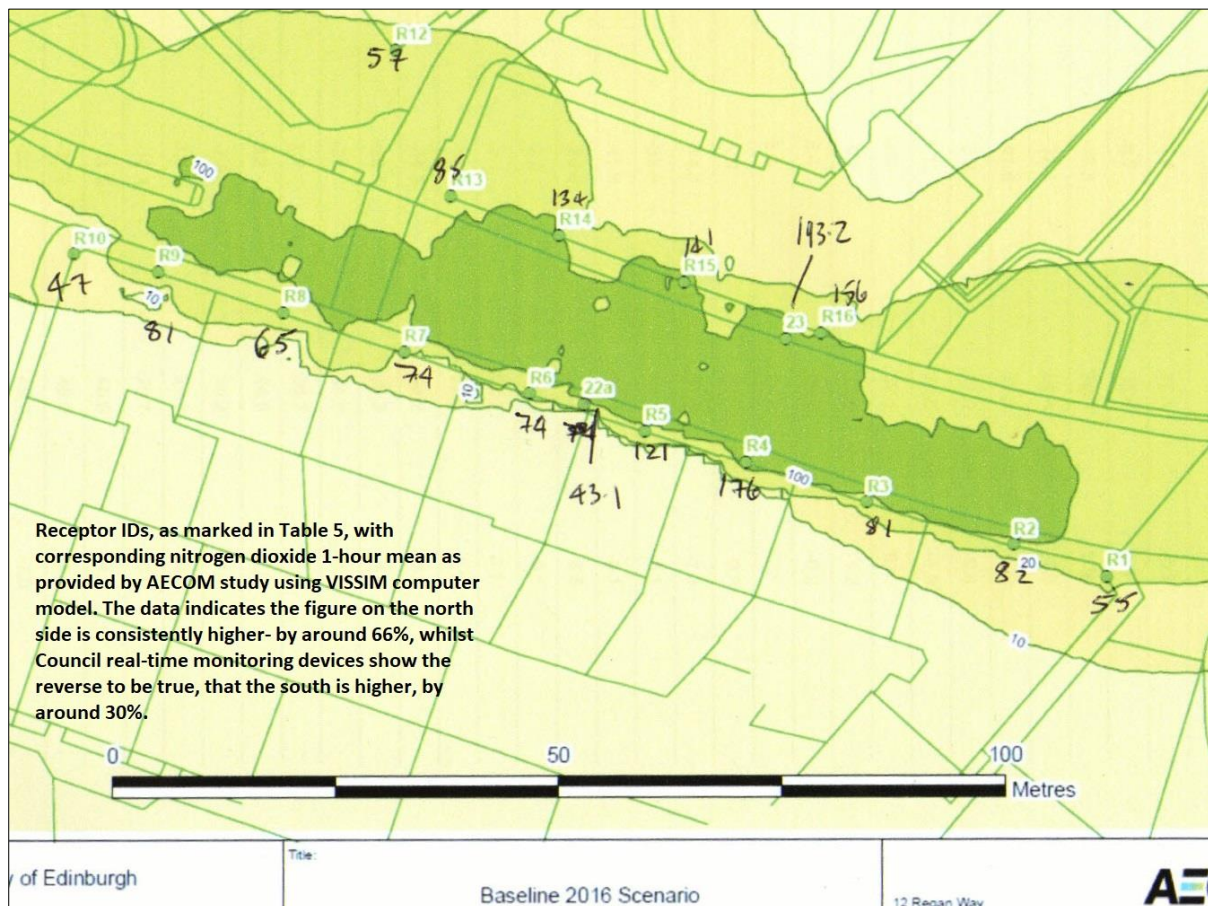

Air Quality Strategy Objectives

Air Quality Strategy Objective for 2005 (NO2) Annual Mean > 40 microgrammes per metre cubed	
Status:	Exceeded
Air Quality Strategy Objective for 2005 (NO2) Hourly Mean > 200 microgrammes per metre cubed for more than 18 hours	
Status:	Not Exceeded

Appendix 4: Modelling study data appears to contradict the monitoring data.

The measured concentrations of nitrogen dioxide on the south side are higher than those on the north side of the street, because Roseburn Terrace is a street canyon. Council monitoring confirms that this is the case. The data from the south side is consistently around 30% greater, as the AECOM Technical Director pointed out at the 15th October meeting. This data is shown in Table 1 above.

However, the report Baseline 2016 Scenario Model shows the receptor IDs, as marked in Table 5, with corresponding NO₂ 1-hour mean as provided by the AECOM study using the VISSIM computer model. The data is claiming the figure on the north side is consistently higher- by an average of around 66%, when we know the reverse is true.

This shows the approach taken for the study bears absolutely no relation to reality. I think this clearly explains why AECOM needed to validate their model - to see if the modelled figures match the monitoring data. And this has not been done. The model hasn't been validated; it needs to be tested against reality, in accordance with [LAQMTG16 Government Guidance](#). The guidance makes clear the ADMS model outputs need to be tested against local monitoring data. The consultant who wrote the report can't do that because there is no hourly monitoring data. So these are plots on a graph that has no scale; the figures have no reference, as they need to be adjusted with respect to real life measures. All we have are computer projections. Which are in fact claiming the opposite that reality tells us.
